ABSTRACT

Background Programmed cell death 1 (PD-1)/programmed death ligand 1 (PD-L1) blockade therapy fails in the majority of patients with cancer. Oncolytic viruses represent a new class of therapeutic agents, yet the therapeutic efficacy is still disappointing. Moreover, intratumoral injection of viruses is the main approach and preclinical studies mainly employ syngeneic or xenograft models.

Methods Use an endogenous mouse lung cancer model that faithfully recapitulates human lung cancer, and various in vivo, ex vivo and in vitro assays, to investigate the efficacy, mechanism of action and resistance of systemically administered oncolytic vaccinia virus (oV), immunotherapy and their combination, to find an effective therapy for refractory lung cancer.

Results Resembling human lung cancers, the majority of which are largely resistant to PD-1/PD-L1 blockade and with decreased PD-L1 expression and T-cell activation by our analysis, urethane-induced endogenous lung tumors in mice show reduced PD-L1 expression, low tumor-infiltrating lymphocytes and innate resistance to PD-1/PD-L1 blockade. Intravenous administration of oV has efficacy and synergizes with simultaneous but not single blockade of PD-1 and T-cell immunoglobulin and mucin-domain containing-3 (TIM-3) in this cancer model. Besides direct tumor cell killing, oV induces T-cell lung recruitment, tumor infiltration, along with expression of PD-1 and TIM-3 on T cells and PD-1 and TIM-3 ligands on tumor cells and tumor-associated immune cells. Blockade of PD-1 or TIM-3 also causes their mutual induction on T cells.

Conclusions While systemic administration of oV shows efficacy in lung cancer by killing tumor cells directly and recruiting and activating T cells for indirect tumor killing, its induction of PD-1 and TIM-3 on T cells and PD-1 and TIM-3 ligands on tumors and tumor-associated immune cells as well as mutual induction of PD-1 or TIM-3 on T cells by their blockade restricts the efficacy of oV or its combination with single PD-1 or TIM-3 blockade. The triple combination therapy is more effective for refractory lung cancer, and possibly other cold cancers as well.

BACKGROUND

Blockade of the ligation of the immune checkpoint PD-1 (also known as CD279) with PD-L1 (also known as B7-H1 or CD274)

using PD-1 or PD-L1 antibody has recently been approved by the Food and Drug Administration as a standard treatment for several cancers, including lung cancer, the leading cause of cancer deaths in both men and women.^{1–3} In general, this revolutionary immunotherapy works better against ‘hot’ tumors, which have abundant infiltrated T cells, strong immunogenicity and sufficient PD-L1 expression. Unfortunately, most tumors are ‘cold’ and do not respond.^{4–7} Even among the most responsive cancer types such as lung cancer, the response rate is only about 20% and resistance may occur after an initial response.^{8–10} Hence, there is a need to explore combination therapies to expand the benefit of this innovative immunotherapy to a greater number of patients.

Oncolytic viruses (OVs) may be an ideal candidate to combine with PD-1/PD-L1 blockade to improve cancer treatment.^{11–15} Currently, several dozen OVs, most of which are armed with granulocyte-macrophage colony-stimulating factor (GM-CSF) or other cytokines, are being evaluated for cancer treatment. Although their safety profile is encouraging, the antitumor efficacy of OVs alone appears to be disappointing.^{12 13 16 17} In addition, local administration and in particular intratumoral injection of OVs, which is the main approach used in both clinical and preclinical studies, also limits their application, particularly for tumors difficult to access, such as lung cancer.

Of note, viruses, including OVs, induce PD-L1 within sites of infection including the tumor microenvironment (TME), and PD-1 on T cells to terminate T-cell activity for immune escape.^{1 18–20} While this PD-L1/PD-1-mediated immune tolerance commonly used by viruses and tumors may account for the disappointing antitumor activity of OVs, it makes OVs an ideal tool to turn cold tumors hot and sensitive to PD-1/PD-L1 blockade,

particularly given additional roles of OV's in inducing T-cell tumor infiltration and tumor immunogenicity. PD-1 blockade should mitigate the PD-L1/PD-1-mediated tumor-promoting function of OV's, thus OV's and PD-1/PD-L1 therapies should synergize to promote tumor clearance. In this regard, virus-associated tumors are known to respond at high rates to PD-1 pathway blockade.²¹

Here, we test whether intravenous administration of vaccinia virus with Double Deletion (vDD) alone, a genetically modified oncolytic vaccinia virus with tumor-selectivity rendered by double deletion of the thymidine kinase gene and the vaccinia growth factor gene,^{16 17 22} has efficacy in refractory lung cancer in an endogenous mouse tumor model that faithfully recapitulates human lung cancer. We also examine whether and how vDD synergizes with blockade of PD-1 and/or TIM-3 (also known as HAVCR2 or CD366), another immune checkpoint that has not yet been approved for clinical use.^{23 24}

METHODS

Animals and cell lines

Mice of BALB/c, FVB/N and C57BL/6 strains were originally from The Jackson Laboratory, and maintained under pathogen-free conditions and used according to protocols approved by Institutional Animal Care and Use Committee of the University of Pittsburgh. Mouse lung cancer cell lines Madison 109 (MAD109), Lewis lung carcinoma (LLC) and LAP0297 were kindly provided by Alan L Epstein (University of Southern California), Per H. Basse/Stephen H. Thorne (University of Pittsburgh) and Dai Fukumura/Peigen Huang (Massachusetts General Hospital and Harvard Medical School), respectively.^{25 26} Human cancer cell lines were described before²⁷ and were cultured at 37°C in humidified 5% CO₂ incubator. Culture medium were supplemented with 10% fetal bovine serum (FBS) and penicillin/streptomycin (Invitrogen, Carlsbad, CA, USA). H23, H460, H727, H1975, H2122 cells were cultured in Roswell Park Memorial Institute (RPMI) 1640 medium. Calu-1 cells were cultured in McCoy's 5a. Calu-6 and SK-LU-1 cells were cultured in Eagle's minimum essential medium. All the other cell lines were cultured in Dulbecco's modified Eagle's medium (DMEM). Cell lines were authenticated by short tandem repeat profiling, and tested for Mycoplasma (last tested in October 2018, IDEXX BioAnalytics).

Viruses and viral infection in vitro

Recombinant Vaccinia virus (Western Reserve strain) vDD was described previously.²² Mouse or human cells (4×10⁵) were seeded in six-well plates overnight and then infected with vDD at MOI of 1.0 in 0.6 mL of 2% FBS-containing DMEM for 2 hours. Growth medium (1.4 mL) was added and the cells were collected around 72 hours post virus infection.

In vitro tumor antigen-dependent T-cell activation and tumor cell killing

As previously described,²⁸ bone marrow-derived dendritic cells (BMDCs) from BALB/c mice were pulsed with the lysates (filtered with Amicon Ultra-15 50K Centrifugal Filter, MilliporeSigma, Burlington, Massachusetts, USA) of the detached MAD109 cells 18 hours post in vitro infection with vDD (1:3 ratio). As controls, PBS mock-treated MAD109 cells as well as vDD-infected or PBS mock-treated normal lung epithelial cells from BALB/c mice were also included in parallel. Pulsed BMDCs were then cocultured with splenic CD3⁺ T cells from BALB/c mice (1:5 ratio) in the presence of interleukin-2 (50 U/mL) for 4 days, followed by fluorescent activated cell sorting (FACS) analysis to detect interferon γ (IFN γ)⁺, granzyme B⁺ and CD69⁺ CD8⁺ T cells. T cells isolated from BMDC coculture were further cocultured with MAD109 or LLC cells stably expressing luciferase (20:1 ratio) for 4 hours, followed by luciferase activity measure in the supernatant (indication of cell apoptosis, as luciferase can be released into the medium only after cell death).

Lung tumor models

Urethane model: As described before,²⁹ female FVB/N mice aged 6–8 weeks were intraperitoneally (i.p.) injected with urethane (1 g/kg body weight, Sigma-Aldrich, St. Louis, Missouri, USA) once a week for six consecutive weeks. Mice were then treated with vDD (intravenous injection, 10⁸ pfu/mouse), PD-1 and/or TIM-3 neutralizing antibodies (i.p. injection, 3 times/week, 200 μ g/mouse/time for PD-1 antibody, 100 μ g/mouse/time for TIM-3 antibody, BioXCell, West Lebanon, New Hampshire, USA). All mice were sacrificed for lung tumor examinations 2 weeks post vDD treatment. Surface tumors in mouse lungs were counted by three blinded readers under a dissecting microscope, and tumor diameters were measured by microcalipers. The volume of each tumor was calculated as $(\pi/6) \times D^3$ (D, tumor diameter). Tumor burden of each mouse was calculated as the sum of the volumes of each tumor in all the lung lobes of that mouse.

Syngeneic model: essentially as described before,³⁰ 6-week-old female FVB/N or BALB/c mice were challenged subcutaneously (s.c.) in the right flank with 10⁶ LAP0297 or MAD109 cells, respectively. Eight days post-tumor cell inoculation, tumors were injected with vDD (10⁸ pfu/mouse) or PBS. Tumors were measured every 2 days post-tumor cell injection. The volume of each tumor was calculated as $(\pi/6) \times \text{width}^2 \times \text{length}$. All the mice were sacrificed 16 days post-tumor cell injection and tumor masses were dissected for further analysis. The effects of PD-1 and TIM-3 blockade alone or together with vDD treatment on syngeneic LAP0297 tumors and mouse survival were also examined. The LAP0297 tumors were injected with vDD (10⁸ pfu/mouse) or PBS 8 days post-tumor cell inoculation, and/or treated with PD-1 and TIM-3 neutralizing antibodies or control PBS starting 9 days post-tumor cell inoculation (i.p. injection

every other day, 200 µg/mouse/time for PD-1 antibody, 100 µg/mouse/time for TIM-3 antibody, BioXCell, West Lebanon, New Hampshire, USA).

Flow cytometry (FACS) analysis

The cells were incubated with the antibodies against cell surface antigens after blocked with αCD16/CD32. The cells were then fixed with paraformaldehyde (2%), permeabilized and incubated with antibodies against intracellular antigens when needed. For IFNγ staining, cells were treated with phorbol 12-myristate 13-acetate (50 ng/mL), ionomycin (1 µM), brefeldin A (3 µg/mL) and monensin (2 µM) for 4 hours before they were stained for FACS analysis. Data were acquired and analyzed by Accuri C6 (BD Biosciences, Bedford, Massachusetts, USA) as described previously³¹ or acquired by LSRFortessa (BD Biosciences) and analyzed by FlowJo software. Immune cells (CD45⁺) were gated with the indicated markers as follows. Lymphocytes were gated for CD4⁺ T cell (CD3⁺CD4⁺CD8⁻), CD8⁺ T cell (CD3⁺CD4⁻CD8⁺), natural killer (NK) cell (NKp46⁺CD3⁻) and B cell (B220⁺CD3⁻). Myeloid cells were gated sequentially as follows: neutrophil (CD11b⁺Ly6G⁺), macrophage (Mac: MerTK⁺CD64⁺; CD11c⁺ Mac: CD11c⁺CD11b⁻; double⁺ Mac: CD11c⁺CD11b⁺; CD11b⁺ Mac: CD11c⁻CD11b⁺), DC (major histocompatibility complex class II (MHC-II)⁺CD11c⁺), monocyte (Mono: CD11b⁺SSC^{lo}; inflammatory monocyte (iMono): Ly6C^{hi}; resident monocyte (rMono): Ly6C^{lo}).

Histology and immunohistochemistry assays

As described previously,^{32,33} mouse or human tissues were excised, fixed in formalin, embedded in paraffin, and cut into 5-µm-thick sections. Sections were stained with H&E, or subjected to sequential incubations with different primary antibodies, biotinylated secondary antibody, and streptavidin-HRP. Antibodies used for histology and FACS assays were listed in online supplementary additional file 2: online supplementary table S1.

Quantitative PCR analysis

The indicated tissues or cells were subjected to RNA extraction, RNA reverse transcription and real-time PCR as described.^{34,35} Primer pairs used for quantitative PCR were listed in online supplementary additional file 2: online supplementary table S2.

STATISTICAL ANALYSIS

Student's t-test (two tailed, unpaired unless otherwise specified) was used to assess significance of differences between two groups. Log-rank test was used to compare survival between treatment groups. All bars in figures represent means±SEM. The sample values for FACS and immunohistochemistry (IHC) quantifications are the numbers of mice and tumors used for the assays, respectively. The p values are indicated as *p<0.05, **p<0.01, ***p<0.001, ****p<0.0001, ns, not statistically significant.

The p values <0.05 and <0.01 are considered statistically significant and highly statistically significant, respectively.

RESULTS

Downregulation of PD-L1 in the majority of human lung cancers

To determine why most human lung cancers do not respond well to PD-1 pathway blockade therapy, we analyzed The Cancer Genome Atlas (TCGA) databases for PD-L1 expression in human lung cancers. PD-L1 expression level in tumor tissues is one most commonly used and reliable biomarker for PD-1 and PD-L1 blockade therapy.^{6–9} Whereas PD-L1 was upregulated in about 11% of human lung cancers, it was downregulated in more than 60% of all human lung cancer cases compared with normal lung tissues (figure 1A; online supplementary additional file 1: online supplementary figure S1a-c). This finding was confirmed with IHC staining of two independent tumor tissue arrays demonstrating that PD-L1 was only detected in ~25%–30% of human lung tumors.³⁶ Analysis of European Molecular Biology Laboratory-European Bioinformatics Institute (EMBL-EBI) Expression Atlas databases also revealed that PD-L1 was repressed in about 60% of human lung cancer cell lines (figure 1B). These findings were further validated in our human lung cancer and cell line studies (figure 1C-E; online supplementary additional file 1: online supplementary figure S1d,e).

To figure out the mechanism of PD-L1 repression in lung cancer, we analyzed the TCGA data for the methylation status of the *pd-l1* promoter in human lung cancers. In line with our recent studies showing that all three functional DNA methyltransferases are increased in human lung cancers,³⁷ we found that the methylation of the *pd-l1* promoter was increased in human lung cancers compared with normal lung tissues (online supplementary additional file 1: online supplementary figure S1f). Consistently, the demethylating agent 5-aza-dC induced expression of PD-L1 in lung cancer cells in vitro (online supplementary additional file 1: online supplementary figure S1g). We also found that T-cell activation and IFN signature gene expression was downregulated in human lung cancers and that IFNγ induced PD-L1 expression in lung cancer cells^{37,38} (online supplementary additional file 1: online supplementary figure S1h-j). These data indicate that PD-L1 downregulation in lung cancer involves its promoter epigenetic repression and inflammation downregulation within the TME.

Similar to PD-L1, PD-L2 (also known as B7-DC or CD273), the other known ligand of PD-1, was also suppressed in most lung cancers (online supplementary additional file 1: online supplementary figure S2). These data together suggest that resistance to PD-1 blockade in most lung cancer patients may involve the downregulation of PD-L1 and PD-L2.

Figure 1 PD-L1 is downregulated in the majority of human lung cancers and mouse lung cancers, and mouse lung cancers induced by urethane are largely resistant to PD-1 blockade therapy. (A) TCGA data showing PD-L1 downregulation in human lung cancer. Left: gray dots and red dots stand for normal lung (NL) tissues and lung tumor (T) tissues, respectively. Right: PD-L1 expression profile in lung cancer tissues. Sample numbers are indicated. (B) EMBL-EBI data showing PD-L1 downregulation in human lung cancer cell lines. (C) Quantitative RT-PCR (qPCR) analysis showing PD-L1 downregulation in human lung cancer. Matched normal lung tissues from the same patients were used as controls. Establishment of a reliable lung cancer model for studying and improving PD-1 therapy

Similar to our human studies, we found that PD-L1 was downregulated in mouse lung cancer cell lines MAD109, LLC and LAP0297, which were originally derived from spontaneous lung tumors developed in BALB/c, C57BL/6 and FVB/N mice, respectively (figure 1F). PD-L1 was also downregulated in mouse primary lung cancers induced by ethyl carbamate (also called urethane), a chemical carcinogen present in fermented food, alcoholic beverage and cigarette smoke (figure 1G,H). It is noteworthy that murine lung cancer induced by urethane faithfully recapitulates human lung cancer, and in particular adenocarcinoma, the most common type of lung cancer that accounts for about 40% of all lung cancers.^{27–29 37 39 40} Moreover, our recent studies have shown that PD-L1 expression can be induced in mouse lung tumor cells both in vitro and in vivo by epigenetic drugs or through immune activation by chemotherapeutic drugs.³⁷ These data demonstrate that mouse lung cancers, like their human counterparts, also share PD-L1 downregulation.

Based on these findings, we tested whether mouse lung cancers induced by urethane, like human lung cancers

with low PD-L1 expression, are also resistant to PD-1 blockade. As expected, they were largely resistant to PD-1 blockade, with no significant changes in both tumor number and tumor burden after PD-1 antibody treatment (figure 1I; online supplementary additional file 1: online supplementary figure S3). Urethane-induced lung cancer in mice thus provides a clinically reliable model of refractory lung cancer that can be used to test new human lung cancer therapies, particularly those that can overcome PD-1 blockade resistance and synergize with PD-1 blockade therapy.

Efficacy of vvDD alone in the treatment of refractory lung cancer

Mice with lung tumors induced by urethane were intravenous injected with vvDD or PBS. Two weeks post vvDD injection, mice were sacrificed, and lung tissues were collected. Compared with the PBS mock-treated group, vvDD-treated mice had a significantly reduced tumor burden in their lungs, although tumor numbers were similar in those mice (figure 2A). Thus, systemic administration of vvDD alone shrinks but does not ablate individual lung nodules in this model of refractory lung cancer. It is

Figure 2 vDd shows efficacy in refractory lung cancer in endogenous and syngeneic mouse lung tumor models. (A) Urethane model showing efficacy of vDd intravenous administration in refractory lung cancer. scale bar, 1 mm. (B) Syngeneic MAD109 lung cancer model showing efficacy of vDd intratumoral injection in refractory lung cancer (n=5). In tumor image, top row: control; bottom row: vDd. (C) Syngeneic LAP0297 lung cancer model showing efficacy of vDd intratumoral injection in refractory lung cancer (n=5). In tumor image, top row: control; bottom row: vDd. (D–F) IHC and FACS showing increased apoptosis by vDd treatment in tumor cells (D), (n=9 and (E), n=3), but no obvious apoptosis in normal lung cells (F) in urethane model. Scale bar, 10 μ m. (G) IHC showing increased tumor cell apoptosis by vDd treatment in syngeneic MAD109 model (n=8). Scale bar, 10 μ m. FACS, fluorescent activated cell sorting; IHC, immunohistochemistry; * p <0.05, ** p <0.01, *** p <0.001, **** p <0.0001; ns, not significant; vDd, vaccinia virus with double deletion.

noteworthy that in line with previous human clinical trial studies showing the promising safety of systemic administration of vDd,¹⁷ no significant side effect of vDd treatment was observed in our mouse studies, as evidenced by no significant changes in mouse weight by the treatment (online supplementary additional file 1: online supplementary figure S4a).

We next repeated the experiment using vDd versus PBS intratumoral injection in syngeneic MAD109 lung cancer model. Tumors form at fast rates in syngeneic models, and importantly, can be monitored easily and daily. Eight days after subcutaneous inoculation of MAD109 cells, vDd or PBS was injected intratumorally. Compared with PBS treatment, vDd treatment led to a significantly reduced tumor burden starting from 2 days post virus treatment (figure 2B). The difference became larger over time, with PBS-treated control tumors continuing to grow, while those treated with vDd almost stopping growing during the remaining experimental period. Similar results were also obtained in syngeneic LAP0297 lung cancer model (figure 2C). These data further supported the efficacy of vDd in treating refractory lung cancer.

Consistent with the anti-lung cancer activity of vDd, significantly higher degrees of apoptosis were detected in lung tumors from vDd-treated mice compared with PBS-treated control mice in both endogenous and syngeneic models (figure 2D–G). No obvious apoptosis was detected within normal lung tissues in either group (figure 2F). Of

note, vDd was only detected in lung tumors but not in normal lung tissues of the vDd-treated mice, supporting vDd selective replication in tumor cells in vivo (online supplementary additional file 1: online supplementary figure S4b). In addition, higher apoptosis was detected in lung cancer cells positive with vDd in comparison to those negative with vDd, suggesting direct killing of tumor cells by vDd infection (online supplementary additional file 1: online supplementary figure S4c). To validate the in vivo studies, we examined in vitro whether vDd selectively kills mouse and human lung cancer cell lines with low PD-L1 expression. Infection with vDd indeed resulted in much more death of both mouse and human lung cancer cells but had no effect on normal lung epithelial cells, further supporting a selective tumor-killing activity of vDd (figure 3A).

In addition to direct oncolysis, another presumptive function of OV is to induce tumor-specific immunity for tumor killing. Thus, we also performed the in vitro assays of lung tumor antigen-dependent T-cell activation and tumoricidal activity.²⁸ Whereas DCs pulsed with vDd-infected normal lung epithelial cells or uninfected lung cancer cells failed to activate T cells, DCs pulsed with vDd-infected lung cancer cells induced strong tumor-specific activation and cytotoxicity of T cells (figure 3B,C). Consistent with these in vitro studies, significantly more CD4⁺ and CD8⁺ T cells expressing the T-cell activation markers IFN γ and CD44 were detected in the lung and

Figure 3 The antitumor actions of vvDD involve direct oncolysis and indirect immune killing of tumor cells. in particular lung tumors of mice treated with vvDD (figure 3D–F). In vivo vvDD treatment also increased both CD4 $^{+}$ and CD8 $^{+}$ T-cell lung recruitment and tumor infiltration (figure 3G,H). It is worthy to note that in this endogenous model lung tumors contained significantly decreased tumor-infiltrating lymphocytes (TILs) compared with normal lung tissues (figure 3G,H; online supplementary additional file 1: online supplementary figure S4d), another major characteristic of cold tumors resistant to PD-1 blockade immunotherapy. Increased tumor infiltration of CD8 $^{+}$ T cells by vvDD treatment was also observed in the syngeneic lung cancer models (online supplementary additional file 1: online supplementary figure S4e). Besides T cells, vvDD treatment also increased tumor infiltration of many other immune cells, such as macrophages, DCs, monocytes, NK cells and B cells (online supplementary additional file 1: online supplementary figure S4f). Interestingly, vvDD treatment

upregulated the expression of the antigen presenting MHC-II on tumor-infiltrating DCs and macrophages as well as the expression of the antibody Fc-gamma receptor (also known as CD64) on tumor infiltrating DCs (online supplementary additional file 1: online supplementary figure S4g). Altogether, these data suggest that vvDD exerts its antitumor activity through both direct oncolysis and indirect immune killing of tumor cells.

No synergy between vvDD and PD-1 or TIM-3 antibody in the treatment of refractory lung cancer

In addition to inducing a strong T-cell activation in the TME, in vivo vvDD treatment also led to increased PD-1 expression on both CD4 $^{+}$ and CD8 $^{+}$ T cells in the lung and in particular on CD8 $^{+}$ T cells in lung tumors (figure 4A,B). Of note, increased percentages of PD-1 $^{+}$ T cells, of both the CD4 $^{+}$ and CD8 $^{+}$ subsets, were observed in the TME compared with adjacent normal lung either

(I) FACS assays of IFNγ and CD44 showing no significant increase in vvDD-induced CD8⁺ T-cell activation by PD-1 antibody treatment in urethane model (n=3). DC, dendritic cell; FACS, fluorescent activated cell sorting; IFNγ, interferon-γ; hi, high; iMono, inflammatory monocyte; IHC, immunohistochemistry; Mac, macrophage; mi, middle; Neu, neutrophil; *p<0.05, **p<0.01, ***p<0.001, ****p<0.0001; ns, not significant; PD-1, programmed cell death 1; PD-L1, programmed death ligand 1; rMono, resident monocyte; SSC, side scatter; vvDD, vaccinia virus with double deletion.

in the presence or absence of the vvDD treatment, suggesting high exhaustion of TILs, since PD-1⁺ CD8⁺ T cells show decreased tumor cell killing ability (online supplementary additional file 1: online supplementary figure S5a). vvDD treatment also induced PD-L1 and PD-L2 expression on tumor cells and tumor-associated immune cells and CD11c⁺ alveolar macrophages in particular (figure 4C–E; online supplementary additional file 1: online supplementary figure S5b). These data suggested that induction of PD-1 expression on T cells and PD-L1 and PD-L2 on tumor cells and tumor-associated immune cells may limit the antitumor activity of vvDD. More importantly, these data together with data shown in figure 3 also suggested that vvDD can convert cold lung cancers into

hot ones that may be sensitive to PD-1 blockade. To test this, we treated mice harboring endogenous lung cancers induced by urethane with both vvDD and PD-1 antibody (figure 4F). The additional treatment with PD-1 antibody had no effect on either tumor number or tumor burden, in comparison to vvDD treatment alone (figure 4G). The tumor cell apoptosis rates were also comparable in vvDD monotherapy and combination therapy (figure 4H).

Surprisingly, PD-1 antibody treatment did not further enhance CD8⁺ T-cell activation (figure 4I), despite increased percentages of PD-1⁺ T cells and increased PD-L1 and PD-L2 expression on tumor cells and tumor associated immune cells after vvDD treatment. Nevertheless, these data suggested that vvDD alone and/or in

(H) FACS assays showing no significant changes in CD4⁺ and CD8⁺ T-cell activation by TIM-3 antibody treatment in urethane model. (I) IHC showing no enhanced tumor cell apoptosis by TIM-3 antibody treatment in urethane model (n=9). Scale bar, 10 μm. (J) FACS assays showing increased PD-1 expression on CD4⁺ and CD8⁺ T cells by TIM-3 antibody treatment alone or together with vDd in urethane model. FACS, fluorescent activated cell sorting; IHC, immunohistochemistry; *p<0.05, **p<0.01, ***p<0.001, ****p<0.0001; ns, not significant; PD-1, programmed cell death 1; TIM-3, T-cell immunoglobulin and mucin-domain containing-3; vDd, vaccinia virus with double deletion.

combination with PD-1 antibody also activates additional mechanism(s) other than PD-1/PD-L1/PD-L2 induction to restrict T-cell activation by vDd. To this end, we examined whether vDd treatment induces expression of TIM-3 and lymphocyte-activation gene 3 (LAG-3, also known as CD223) on T cells. Like PD-1, TIM-3 and LAG-3 are well-known immune checkpoints that mediate T-cell exhaustion, particularly that of CD8⁺ T cells.^{23 24 41–44} We found that vDd treatment significantly upregulated TIM-3 expression on CD8⁺ T cells but not CD4⁺ T cells in the lungs and in particular lung tumors (figure 5A–C;

online supplementary additional file 1: online supplementary figure S6a). Combination with PD-1 antibody further increased TIM-3 expression on CD8⁺ T cells (figure 5C). In addition, vDd alone or together with PD-1 antibody significantly increased the expression of the TIM-3 ligands phosphatidylserine (PtdSer), carcinoembryonic antigen-related cell adhesion molecule 1 (CEACAM1, also known as CD66a) and high mobility group box 1 (HMGB1) on tumor cells and/or tumor-associated CD11c⁺ alveolar macrophages but had no effect on the expression of Galectin-9, another known ligand

for TIM-3 (online supplementary additional file 1: online supplementary figures S4c, S6b-d). However, vvDD alone or together with PD-1 antibody had no effect on LAG-3 expression on either CD8⁺ or CD4⁺ T cells as well as the expression of the LAG-3 ligand liver and lymph node sinusoidal endothelial cell C-type lectin (LSECtin, also known as C-type lectin superfamily 4, member G, CLEC4G) on tumors (figure 5D–F; online supplementary additional file 1: online supplementary figure S7a), although those treatments induced the expression of fibrinogen-like protein 1 (FGL1) and MHC-II, two other known ligands of LAG-3, on tumor cells and tumor-infiltrating DCs and macrophages, respectively (online supplementary additional file 1: online supplementary figure S7b,c).

Accordingly, we tested whether TIM-3 blockade enhances the therapeutic effect of vvDD. We also tested whether TIM-3 antibody alone has any therapeutic effect on refractory lung cancer, as a control. Of note, the role of TIM-3 blockade in lung cancer treatment has not been well defined yet. In line with the relatively low basal expression of TIM-3 on TILs (figure 5B), treatment with TIM-3 antibody had no significant therapeutic effect (figure 5G–I), suggesting that lung cancer is also largely intrinsically resistant to TIM-3 blockade. In this regard, our analysis of TCGA data indicated that TIM-3 expression was significantly downregulated in human lung tumor tissues compared with normal human lung tissues (online supplementary additional file 1: online supplementary figure S8). TIM-3 blockade also failed to enhance the therapeutic effect of vvDD, although vvDD treatment could potentially induce TIM-3 expression on CD8⁺ TILs. Mechanistically, we found that treatment with TIM-3 antibody alone or together with vvDD increased PD-1 expression on CD4⁺ and CD8⁺ T cells (figure 5J). These data together suggested that simultaneous induction/activation of PD-1 and TIM-3 by vvDD and mutual induction of PD-1 and TIM-3 by their blockade contribute to the restriction of vvDD's antitumor activity and the failure of synergy between vvDD with single blockade of PD-1 or TIM-3 in lung cancer treatment.

Improvement of vvDD viro-immunotherapy by dual blockade of PD-1 and TIM-3

We next tested whether dual blockade of PD-1 and TIM-3 improves the efficacy of vvDD in refractory lung cancer in the endogenous lung cancer model, with a treatment schedule identical to figure 4F, with the addition of anti-TIM3 concurrent with anti-PD-1. Similar to single blockade, dual blockade of PD-1 and TIM-3 only showed minimal therapeutic effect (figure 6A). However, PD-1 and TIM-3 dual blockade combined with vvDD showed great synergy. In comparison to vvDD treatment alone, combination with both PD-1 and TIM-3 antibodies led to significantly reduced tumor burden, and importantly, significantly reduced tumor number, suggesting not only an overall tumor regression but also complete remission of some tumors. PD-1 and TIM-3 dual blockade also showed minimal therapeutic effect but great synergy

when combined with vvDD in syngeneic lung cancer model, as evidenced by both tumor growth curve and animal survival rate (figure 6B,C). Dual blockade of PD-1 and TIM-3 also significantly increased activation of both CD4⁺ and CD8⁺ T cells and apoptosis of tumor cells by vvDD (figure 6D–F). These preclinical data suggest that combination of vvDD with dual blockade of PD-1 and TIM-3 may be effective for the treatment of human lung cancers, particularly those resistant to PD-1/PD-L1 or TIM-3 blockade.

DISCUSSION

Lung cancer is the no. 1 cancer killer, with about 234 000 new cases and 154 000 deaths yearly in the USA alone.⁴⁵ Recently, PD-1/PD-L1 blockade immunotherapy has been approved for treatment of lung and several other cancers.^{1–10} While some patients have shown dramatic responses, the majority of patients do not benefit. Our human data studies indicate that PD-L1 is upregulated in only a minority of cancer cases, and downregulated in the majority of lung cancers. Moreover, T-cell activation within the TME is downregulated in most human lung cancers. These may account for the low response rate of PD-1 pathway blockade therapy in lung cancer patients. Paradoxically, PD-1 is upregulated in most human lung cancers (online supplementary additional file 1: online supplementary figure S9). Applying an endogenous mouse lung cancer model that closely resembles human lung cancer in genetics, molecular and immunological biology, as well as morphology and histology,^{27–29 37 39 40} we observed PD-L1 downregulation and low TILs with increased PD-1 expression as well as overall resistance to PD-1 blockade therapy similar to humans. Using this preclinical model, we show that OVVs can be used to treat refractory lung cancers as monotherapy, and more importantly, to turn cold lung tumors hot for better combination treatment.

In addition to inducing tumor cell lysis to trigger tumor-specific T-cell recruitment/infiltration and activation for further tumor cell killing, OVVs stimulate PD-1 and TIM-3 expression on T cells as well as the expression of PD-1 and TIM-3 ligands on tumor cells and tumor-associated immune cells, inhibiting antitumor T-cell activation. Consistent with their redundant function in T-cell repression, blockade of either PD-1 or TIM-3 alone fails to enhance the therapeutic efficacy of OVVs. PD-1 blockade further increases TIM-3 expression on T cells, and TIM-3 blockade alone or together with OVVs induces PD-1 expression on T cells, providing rationale for the failure to combine OVVs with either PD-1 or TIM-3 antibody individually for improved therapeutic efficacy. Simultaneous blockade of both PD-1 and TIM-3 significantly enhances T-cell activation and therapeutic efficacy of OVVs, suggesting a new combination therapy for lung and other refractory cancers.

Given that upregulation of the PD-1 and TIM-3 pathways underlies viral immune escape,^{24 41} although increasing

Figure 6 Dual blockade of PD-1 and TIM-3 synergizes with vvDD in treating refractory lung cancer. (A) Urethane model showing no significant efficacy of PD-1 and TIM-3 dual blockade alone but a synergy with vvDD in treating refractory lung cancer. scale bar, 1 mm. (B, C) Tumor growth (B) and mouse survival analysis (C) showing no significant efficacy of PD-1 and TIM-3 dual blockade alone but a synergy with vvDD in syngeneic LAP0297 lung cancer model. Note, mice died before day 16 in the control (Ctrl) group were not included for the tumor volume calculation at the day 16 timepoint. (D) FACS assays of IFN γ showing increase in the percentage of activated pulmonary CD4⁺ and CD8⁺ T cells by combination therapy in urethane model. (E) FACS assays showing increase in the number of activated pulmonary CD4⁺ and CD8⁺ T cells by combination therapy in urethane model. (F) IHC showing increased tumor cell apoptosis by combination therapy in urethane model (n=9). Scale bar, 10 μ m. FACS, fluorescent activated cell sorting; IFN γ , interferon γ ; IHC, immunohistochemistry; *p<0.05, **p<0.01, ***p<0.001, ****p<0.0001; ns, not significant; PD-1, programmed cell death 1; TIM-3, T-cell immunoglobulin and mucin-domain containing-3; vvDD, vaccinia virus with double deletion.

antitumor immunity, blockade of PD-1 and TIM-3 may also release the brake on the antiviral immune response, speeding up virus clearance. Thus, it is better not to start to administer PD-1 and TIM-3 antibodies simultaneously with or immediately after OV administration. This will allow OVs to replicate, spread, and enhance tumor killing prior to enhanced viral clearance from PD-1 and TIM-3 blockade. Our studies also indicate that PD-1 and TIM-3 antibodies should be used together and simultaneously, because they both are induced by OVs, and importantly, blockade of one of them is not only ineffective but also leads to upregulation of the other one on T cells, leading to T-cell suppression and diminution of antitumor activity.

Mouse studies on OVs mainly use syngeneic models. Although informative, syngeneic models are not ideal for studying cancer immunology and immunotherapy, because they do not resemble the natural co-evolution of tumor and immune cells.⁴⁶ They can induce acute

immune response with fundamental differences from chronic immune responses in endogenous tumors. For example, MAD109 lung cancer cells, which were originally obtained from a cold tumor with minimal PD-L1 expression, can form hot tumors with high PD-L1 expression and infiltrating T cells after being s.c. inoculated into syngeneic mice (online supplementary additional file 1: online supplementary figure S10). Syngeneic tumor models may also show some fundamental differences in response to OVs, although they, like the endogenous mouse lung tumor model, may increase PD-1 expression on T cells and PD-L1 on tumor cells and tumor-associated immune cells after OV intratumoral injection (online supplementary additional file 1: online supplementary figure S11a, b). Unlike in the endogenous lung tumor model, OV administration does not upregulate but instead decreases the percentages of TIM-3⁺ TILs in the MAD109 syngeneic model. Accordingly, in contrast to

the endogenous urethane lung tumor model described here, PD-1 blockade and OV's show therapeutic synergy in this syngeneic lung tumor model as well as in syngeneic colon and ovarian tumors.^{47–50} The upregulation of TIM-3 in the presence of OV's as seen in the endogenous model may represent a more relevant physiologic scenario, as upregulation of both PD-1 and TIM-3 on T cells by several different viruses has been described under non-tumor conditions.^{23 24 41–44} Our studies also suggest that the LAP0297 syngeneic lung tumor model may be a better alternative for studying refractory lung cancers compared with the MAD109 model, as it, like the endogenous lung cancer model, also shows TIM-3 induction on CD8⁺ TILs by OV administration (online supplementary additional file 1: online supplementary figure S11c, d).

CONCLUSIONS

In summary, we find that PD-L1 and T-cell activation are downregulated in a majority of human lung cancers, and that urethane-induced lung tumor in mice is a reliable endogenous model of human lung cancer with decreased PD-L1 expression and low TILs and innate resistance to PD-1/PD-L1 blockade. Using this preclinical model of lung cancer and various in vivo, ex vivo and in vitro assays, we find that intravenous administration of OV's promotes tumor cell death by the dual mechanisms of direct tumor cell killing and inducing T-cell tumor infiltration and activation, along with increasing expression of PD-1 and TIM-3 on T cells and PD-1 and TIM-3 ligands on tumor cells and tumor-associated immune cells. We have described here that single blockade of either PD-1 or TIM-3, particularly when being combined with OV treatment, increases the expression of the other one on T cells. These findings help to characterize lung cancer resistance to oncolytic viro-immunotherapy combined with either PD-1 or TIM-3 blockade alone. However, OV's combined with both PD-1 and TIM-3 blockade were highly effective in our model, providing a strong rationale for the triple combination therapy for refractory lung cancer and possibly other cancer types, particularly those cold tumors otherwise resistant to treatment.

Acknowledgements The authors thank A.L. Epstein, P.H. Basse/S.H. Thorne, and D. Fukumura/P. Huang for providing MAD109, LLC cells and LAP0297, respectively. The authors also thank Y. Xiao and X. Chu for technical assistance.

Contributors ZQ and GX conceived and designed the study, led and contributed to all aspects of the analysis, and wrote the manuscript. FS performed the experiments. ZSG provided the oncolytic vaccinia virus and advice. ADG and SDS provided advice and constructive feedback.
