ABSTRACT

Background Preclinical data suggest cell cycle checkpoint blockade may induce an immunostimulatory tumor microenvironment. However, it remains elusive whether immunomodulation occurs in the clinical setting. To test this, we used blood and fresh tissue samples collected at baseline and post therapy from a phase II trial of the cell cycle checkpoint 1 inhibitor (CHK1i) prexasertib in recurrent ovarian cancer.

Methods Paired blood samples and fresh core biopsies, taken before treatment was started at baseline (cycle 1 day 1 (C1D1)) and post second dose on day 15 of cycle 1 (C1D15), were collected. To evaluate changes in the immune responses after treatment, multiparametric flow cytometry for DNA damage markers and immune cell subsets was performed on paired blood samples. RNA sequencing (RNAseq) of paired core biopsies was also analyzed. Archival tissue immune microenvironment was evaluated with immunohistochemistry. All correlative study statistical analyses used two-sided significance with a cut-off of $p=0.05$.

Results Flow cytometric analysis showed significantly increased γ -H2AX staining after CHK1i treatment, accompanied by increased monocyte populations, suggestive of an activated innate immune response (median 31.6% vs 45.6%, $p=0.005$). Increased expressions of immunocompetence marker HLA-DR (Human Leukocyte Antigen DR antigen) on monocytes and of *TBK1*, a marker of STING (stimulator of interferon genes) pathway activation, in biopsies were associated with improved progression-free survival (PFS) (9.25 vs 3.5 months, $p=0.019$; 9 vs 3 months, $p=0.003$, respectively). Computational analysis of RNAseq data indicated increased infiltration of tumor niches by naïve B-cells and resting memory T-cells, suggestive of a possibly activated adaptive immune response, and greater T-reg infiltration after treatment correlated with worse PFS (9.25 vs 3.5 months, $p=0.007$). An immunosuppressive adaptive immune response, perhaps compensatory, was also observed on flow cytometry, including lymphodepletion of total peripheral CD4+ and CD8+ T cells after CHK1i and an increase in the proportion of T-regs among these T-

cells. Additionally, there was a trend of improved PFS with greater tumor-infiltrating lymphocytes (TILs) in archival tissues (13.7 months >30% TILs vs 5.5 months ≤30% TILs, $p=0.05$).

Conclusion Our study demonstrates that a favorable clinical response in high-grade serous ovarian carcinoma patients treated with CHK1i is possibly associated with enhanced innate and adaptive immunity, requiring further mechanistic studies. It is supportive of current efforts for a clinical development strategy for therapeutic combinations with immunotherapy in ovarian cancer.

BACKGROUND

Ovarian carcinoma accounts for the majority of gynecologic cancer deaths in the USA.¹ High-grade serous ovarian carcinoma (HGSOC) is the most common subtype of ovarian cancer and typically presents as advanced disease with a high frequency of recurrence, requiring new effective therapeutic strategies. The molecular characteristics of HGSOC include universal *TP53* dysfunction that disrupts the G1-S cell cycle checkpoint. This leaves the cells heavily dependent on cell cycle checkpoint-mediated G2-M arrest for DNA repair.² Cell cycle checkpoint kinase 1 (CHK1), which regulates the G2-M checkpoint, is overexpressed in nearly all HGSOC,³ making it a rational target to induce DNA damage and tumor cell death.

CHK1 is activated by the ataxia telangiectasia and Rad3-related (ATR) and ataxia-telangiectasia mutated (ATM) kinases in response to DNA damage or replication stress.⁴ On activation, CHK1 phosphorylates and inhibits its substrates, M-phase inducer phosphatases 1 (CDC25A) and 3 (CDC25C), which led to cell cycle arrest at the G2-M checkpoint.^{4–6} This allows for DNA damage

repair and stabilization of stalled replication forks, without which double-stranded DNA breaks and consequent cell death would occur.⁷ Prexasertib, the second-generation CHK1 inhibitor (CHK1i), has been reported to induce DNA damage and apoptosis in numerous preclinical models including ovarian cancer.^{8–10}

Preclinical data also suggest that the efficacy of CHK1 inhibition may be associated with innate and adaptive immunomodulation, although studies are limited, particularly in ovarian cancer. It has been shown that both CHK1 and ATR activation after DNA damage leads to upregulation of programmed death ligand-1 (PD-L1),^{11,12} potentially via the STAT/IRF1 pathway.¹² In vitro work in osteosarcoma, prostate and lung cancer models demonstrated that PD-L1 expression induced by ionizing radiation-related DNA damage was thereby downregulated by CHK1i.¹² ATR inhibition also has been shown to decrease PD-L1 expression, sensitizing tumor cells to T-cell-mediated killing.¹¹ Recently, Sen *et al.*¹³ reported that DNA repair inhibition, such as with the CHK1i prexasertib, causes increased DNA damage and accumulation of broken DNA fragments in the cytoplasm. Cytosolic DNA fragments can then bind to cyclic GMP-AMP synthase (cGAS), leading to upregulation of the cGAS-stimulator of interferon genes (STING) pathway.^{13,14} The STING pathway is a potent activator of type I interferons (IFN) and elicits both innate and adaptive anti-tumor immune responses, including increased production of immunostimulatory cytokines and recruitment of T-cells.^{13–18}

However, while CHK1 inhibition enhanced anti-tumor CD8+T cell infiltration, it was also reported to increase endogenous immunosuppressive PD-L1 expression, enabling synergy with anti-PD-L1 therapy.¹³ These varying results reflect a complex biology as well as different experimental conditions and thus highlight the need for further studies in the context of immunomodulation in the clinical setting. We recently reported promising clinical activity of the CHK1i prexasertib in heavily pre-treated *BRCA* wild-type (*BRCA*wt) patients with recurrent ovarian cancer.¹⁹ In the present study, we hypothesized that CHK1i may have induced both innate and adaptive immune responses in addition to its effect on the cell cycle regulation, thus contributing to the observed clinical activity in ovarian cancer patients. To test this hypothesis, we investigated changes in the peripheral and tumoral innate and adaptive immune responses in patients treated with CHK1i monotherapy using paired pre-treatment and post-therapy blood and tissue samples. We now report the increases in cellular and molecular markers of innate and adaptive immunity by CHK1i monotherapy that correlated with a favorable clinical response.

METHODS

Patients and study design

This single arm proof-of-concept phase II study was approved by the Institutional Review Board of the Center

Figure 1 Study schema and increased γ -H2AX, possibly caused by CHK1i. (A) Prexasertib was administered intravenously at 105 mg/m² every 2 weeks in 28-day cycles until disease progression or unacceptable toxicities. A mandatory baseline tumor biopsy was performed before C1D1 treatment, and an optional second biopsy was performed 6 to 24 hours after treatment on C1D15. PBMCs for flow cytometry were collected at C1D1 and 6 to 24 hours after treatment on C1D15. (B) Flow cytometric analysis showing increased MFI of γ H2AX in PBMC isolated from patients before (pre) and after a 2-week treatment with prexasertib (post). Cells were first gated on CD3 (T-cells), CD19 (B cells), or CD56 (NK cells) prior to plotting for γ H2AX. C1D1, cycle 1 day 1; C1D15, cycle 1 day 15; MFI, mean fluorescence intensity; NK, natural killer; PBMCs, peripheral blood mononuclear cells.

for Cancer Research (CCR), National Cancer Institute (NCI), Bethesda, Maryland, USA, and written informed consent was obtained from participating patients. Comprehensive enrollment criteria have previously been published.¹⁹ Briefly, eligible patients had recurrent HGSOC, an Eastern Cooperative Oncology Group (ECOG) Performance Status of 0 to 2 and good end-organ function. The *BRCA*wt HGSOC cohort completed enrollment in November 2016 for which details were published and data from that cohort are used for this pilot project.¹⁹ The *BRCA* mutation HGSOC cohort is currently enrolling the patients (NCT02203513). There was no limit on number of prior therapies, however, patients had to have at least 4 weeks wash-out period from their last treatment. Clinical study details, including drug administration, safety, adverse events, and tumor response in the *BRCA*wt HGSOC cohort have been reported¹⁹ and the schema for treatment is shown in figure 1A. Paired blood samples, taken before treatment was started at baseline (cycle 1 day 1 (C1D1)) and 6 to 24 hours post second dose on day 15 of cycle 1 (C1D15), were collected from all patients. Pre-treatment and C1D15 percutaneous core biopsies were obtained by interventional radiologists under CT or ultrasound guidance using local anesthesia. All core biopsy samples were processed immediately in

real time into optimal cutting temperature compound and stored at -80°C prior to analysis. Paraffin-embedded archival tissue samples from the time of original diagnosis were obtained at trial enrollment for immunohistochemistry as fresh frozen biopsy samples did not yield evaluable immunohistochemistry findings.

Flow cytometry

Cells were incubated with Fc receptor blocking agent (Miltenyi Biotec, Bergisch Gladbach, Germany) and stained with monoclonal antibodies for 20 min at 4°C . For intracellular staining for Foxp3 and Ki67 expression, cells were fixed and permeabilized using a Fix/Perm buffer (eBioscience, San Diego, California, USA) according to the manufacturer's instructions, then stained with anti-Foxp3 or anti-Ki67 antibody. Live cells were discriminated by means of LIVE/DEAD Fixable Aqua Dead Cell Stain (Life Technologies, New York, USA) and dead cells were excluded from the analysis. All analyzes were performed using multiparametric flow cytometry (MACSQuant; Miltenyi Biotec, Bergisch Gladbach, Germany) and data were analyzed using FlowJo software V.10.0.7 (FlowJo, LLC, Ashland, Oregon, USA). Gating was first performed on peripheral blood mononuclear cells (PBMCs) with doublet exclusion and then on viable cells. CD8+ or CD4+T cells were further gated for functional markers PD-1, glucocorticoid-induced TNFR-related protein (GITR), Human Leukocyte Antigen DR antigen (HLA-DR), inducible T-cell costimulatory (ICOS) or Ki-67. Monocytic myeloid-derived suppressor cells (M-MDSCs) were defined as CD11b+CD14+HLA-DR-CD15-, early-stage MDSCs (E-MDSCs) as CD11b+CD3-CD14-CD15-CD19-CD56-HLA-DR-CD33+ and polymorphonuclear MDSCs (PMN-MDSCs) as CD11b+CD14 CD15+. For monocytes, total monocytes were subdivided by CD14 and CD16 expression: classical monocytes (CD14 ++CD16-); non-classical monocytes (CD14 +CD16++); and intermediate monocytes (CD14 ++CD16+). Representative figures describing detailed flow cytometry gating strategies can be found in online supplemental figure 1. The monoclonal antibodies used (all from BioLegend, San Diego, California, USA) are listed in online supplemental table 1.

RNA sequencing

Total RNA was isolated from pre-treatment and available C1D15 fresh-frozen core biopsies using the RNeasy microkit (Qiagen). RNA quality was evaluated using the Agilent Bioanalyzer 2100 and RNA integrity number (RIN) values were ensured to be >8.0 . For total RNA sequencing (RNAseq), each sample (20 to 100 ng) was preprocessed with NEBnext rDNA depletion kit (New England Biolabs, Ipswich, Massachusetts, USA) to remove ribosomal RNA, then barcoded and pooled to ensure at least 100 million reads per sample on a HiSeq3000 sequencing system (Illumina, San Diego, California, USA). The human reference genome Hg38 was used to align reads and gene expression data were generated as

counts per million mapped reads (CPM) values. Quality check of sample and sequencing outputs were performed by the CCR sequencing facility and CCR collaborative bioinformatics resource at NCI, Bethesda, Maryland, USA. As previously described,¹⁹ RNAseq data of normal ovarian tissues were obtained from the Genotype-Tissue Expression project (GTEx project, NIH; <https://www.gtexportal.org/home/>, last accessed on January 13, 2019) as Reads Per Kilobase of transcript per Million mapped reads (RPKM) values and then converted to CPM values using the formula $\text{RPKM}=\text{CPM}/L$, where L is the exonic length in kilobases. Log2 of CPM values were used throughout. Biopsies determined to be derived from normal tissue were excluded from analysis. HGSOc subtype was determined using a validated single sample Gene Set Enrichment Analysis (ssGSEA) signature as has been previously described.^{20 21} IFN- γ and expanded immune gene signature scores (online supplemental table 2) were calculated by averaging the normalized log2 expression levels of the included genes, as described by Ayers *et al.*²² CIBERSORT, a computational algorithm for quantifying immune cell fractions using gene expression profiles, was performed to determine tumorous immune infiltration as previously described.²³

Immunohistochemistry

Pre-treatment formalin-fixed paraffin-embedded (FFPE) tissue samples from 24 patients were sent to Johns Hopkins Hospital for pathologic correlative studies; the tissue from one patient (Study ID 40) was inadequate for correlative studies due to tissue preservation. H&E-stained slides of the tissue samples from the remaining 23 patients were evaluated to confirm the pathologic diagnosis of high-grade ovarian carcinoma and to score the presence of tumor-infiltrating lymphocytes (TILs) and tumor-associated macrophages (TAMs). TIL were scored as the percentage (0% to 100%) of tumor stroma area occupied by mononuclear inflammatory cells, as previously described.²⁴ TILs were not scored in tumor specimens lacking stroma, that is, those specimens consisting entirely of detached fragments of carcinoma cells without interface to adjacent stroma. The presence of TAM was recorded as: score 0 (absent), score 1 (focal, largely confined to papillary cores), score 2 (non-focal, involving both papillary cores and tumorous stroma), and score 3 (diffuse, involving papillary cores, tumorous stroma, and carcinoma cell nests). Immunohistochemistry for CD68 (Clone KP1, Dako; Bond RX, Bond Polymer Refine Detection) was performed on all cases to confirm the histologic impression of TAM.²⁵

Immunohistochemistry for PD-L1 was performed manually on unstained slides (PD-L1 clone SP142, 0.096 $\mu\text{g}/\text{mL}$ concentration; Spring Bioscience, Pleasanton, California, USA), as described.²⁵ Specifically, the Spring Bioscience PD-L1 clone SP142 was used with a laboratory-developed assay validated against the labeling results of comparable assays.²⁵ Briefly, slides were deparaffinized and rehydrated using standard methods. Antigen retrieval was performed

in pH 6.0 CB buffer in a decloaking chamber (Biocare Medical, Pacheco, CA, USA), and slides were treated with peroxidase, protein, avidin, and biotin blocking, and incubated with the primary antibody overnight at 4°C. Slides were then treated with a biotin-labeled anti-rabbit secondary antibody (1 µg/µl concentration). The signal was developed with horseradish peroxidase using the VECTASTAIN Elite ABC Kit (Vector Laboratories, Burlingame, California, USA), amplified using a Tyramide Signal Amplification PLUS Biotin KIT (dilution 1:50; Perkin Elmer, Waltham, Massachusetts, USA), and visualized by 3,3'-Diaminobenzidine (DAB). PD-L1 labeling of carcinoma cells was evaluated in all cases and was scored as percentage (0% to 100%) of malignant cells with membranous labeling, with a cut-off of ≥1% carcinoma cell labeling considered positive.

Statistical analysis

Comparison of correlative markers were performed using a non-parametric Mann-Whitney test (for unpaired analyses) or a non-parametric Wilcoxon matched-pairs signed-rank test (for paired analyses) using GraphPad Prism, V.6. Immunohistochemistry data analyses were performed using Microsoft Excel (t-test) or GraphPad Online (Fisher's exact test). The significance of difference between Kaplan-Meier survival curves was compared with a Mantel-Cox log-rank test. All statistical tests used two-sided significance with a cut-off of $p=0.05$ and are reported without adjustment for multiple comparisons due to the small study cohort and exploratory nature of this analysis.

Study approval

The trial was approved by the Institutional Review Board of the CCR, NCI, Bethesda, Maryland, USA. All patients provided written informed consent before enrollment.

RESULTS

Patients

The treatment schema and correlative studies are shown in [figure 1A](#). Characteristics of the 24 evaluable *BRCA*wt HGSOC patients enrolled in this phase II trial have previously been described in detail¹⁹ and are summarized in [table 1](#). Briefly, in this group of heavily pre-treated patients (median 4.5 prior treatments (1 to 13)), there were eight (33%) partial responses (PR) and six (25%) patients with stable disease (SD) ≥6 months for a clinical benefit rate (CBR; PR+SD ≥6 months) of 58%. For this post hoc exploratory biomarker study, not all patients had available samples from each translational endpoint but 100% of patients had paired pre-treatment and post-treatment blood among which 96% (23/24) were evaluable for flow cytometry, 88% (21/24) had evaluable archival tissue from primary diagnosis, and 38% (9/24) had both paired blood and fresh core biopsy samples from this trial; [table 1](#) also includes the number of patients within each of the substudy elements.

Table 1 Clinical characteristics and numbers in correlative study elements (n=24)

Age (years)	
Median (IQR)	64.0 (58.0 to 69.5)
Number of previous treatments (n, %)	
1	1 (4%)
2	8 (33%)
≥3	15 (63%)
Median (range)	4.5 (1 to 13)
Platinum sensitivity* (n, %)	
Platinum-sensitive	5 (21%)
Platinum-resistant	18 (75%)
Platinum-refractory	1 (4%)
Best RECIST response (n, %)	
PR	8 (33%)
SD ≥6 months	6 (25%)
Total CBR (PR+SD ≥6 months)	14 (58%)
SD <6 months	3 (13%)
PD	7 (29%)
Correlative studies (n, %)	
Tumor biopsies	
Pre-treatment	18 (75%)†
Post-treatment	12 (50%)†
Paired	9 (38%)
Flow cytometry	23 (96%)‡
Immunohistochemistry	21 (88%)§
CBC	24 (100%)

*Platinum-sensitive: recurs 6 or more months after cessation of last platinum-based chemotherapy; platinum-resistant: progression within 6 months of last platinum-based therapy; platinum-refractory: progression while actively on platinum-based therapy. †All 24 patients had baseline biopsies performed, however six were determined to be non-tumor tissue by RNAseq analysis and were excluded from analysis. Thirteen patients had an optional second biopsy performed, and one was determined to be of non-tumor origin and excluded.

‡C1D15 PBMCs from one patient were missing.

§Archival tissue from one patient was exhausted prior to enrollment in the trial and was unevaluable in two patients due to tissue fragmentation and lack of stroma.

CBC, complete blood count; CBR, clinical benefit rate; PBMC, peripheral blood mononuclear cells; PD, progressive disease; PR, partial response; RECIST, Response Evaluation Criteria in Solid Tumors; RNAseq, RNA sequencing; SD, stable disease.

DNA damage in peripheral immune cells

Our findings from paired pre-treatment and post-treatment PBMCs showed an increase in the number of lymphocytes with γ-H2AX staining by flow cytometry, a marker of double-stranded DNA breaks.²⁶ Specifically, we observed increases in median fluorescent intensities (MFIs) of γ-H2AX among CD3⁺ T (median 1.63 vs 1.74, $p=0.03$), CD19⁺ B (median 1.69 vs 1.76, $p=0.04$), and CD56+Natural Killer (NK) lymphocytes (median 1.82 vs

Figure 2 Prexasertib-induced changes in innate immunity. (A) An increase from pre-treatment to post-treatment percent monocytes per total viable cells observed with flow cytometric analysis of 23 paired PBMC samples using the Wilcoxon matched-pairs signed-rank test. Lines denote median and 95% CI. (B) Survival curves were compared using the Mantel-Cox log-rank test. An increase in HLA-DR on total monocytes, seen in 12 of 23 patients, is associated with improved PFS (9.25 vs 3.5 months, $p=0.019$). (C) An increase in HLA-DR on classical monocytes, seen in 9 of 23 patients, is associated with improved PFS (9.5 vs 3.75 months, $p=0.04$). (D) An increase in HLA-DR on non-classical monocytes, seen in 10 of 23 patients, is associated with improved PFS (11.5 vs 4 months, $p=0.002$). (E) Increased expression of TBK1, a key protein in the STING pathway, seen in six of nine patients with paired pre-treatment and post-treatment biopsies, is associated with improved PFS (9 vs 3 months, $p=0.003$). HLA-DR, Human Leukocyte Antigen DR antigen; mono, monocytes, mo, months; PBMC, peripheral blood mononuclear cells; PFS, progression-free survival; STING, stimulator of interferon genes; TBK1, TANK-binding kinase 1.

2.05, $p=0.02$), suggestive of increased DNA damage in patients treated with CHK1i (figure 1B). Moreover, the observed increase in γ -H2AX corresponded to treatment-induced lymphodepletion as nearly 80% of patients experienced grade 3 or 4 reduced white blood cell counts,¹⁹ consistent with previous studies correlating double-stranded DNA damage with peripheral lymphocyte apoptosis.^{27,28} Change in γ -H2AX was not associated with clinical response or progression-free survival (PFS).

Innate immune activation in recurrent ovarian cancer

To evaluate changes in the peripheral innate immune response, immunostimulatory cell (ie, monocyte) and immunosuppressive cell (ie, myeloid-derived suppressor cell (MDSC)), subpopulations were compared in paired PBMC samples (online supplemental table 3). There was an increase in percent monocytes per total viable cells (median 31.6% (pre) vs 45.6% (post), $p=0.005$, figure 2A) after CHK1i treatment, although this did not correlate with clinical response or PFS. However, an increase in the immunocompetence functional marker HLA-DR on total monocytes, seen in 12 of 23 patients (MFI fold-increase 1.15 (1.01 to 2.76)), was associated with improved PFS (9.25 vs 3.5 months, $p=0.019$, figure 2B) suggesting innate immune activation of monocytes may contribute to the clinical efficacy of CHK1i. Similarly, an increase in HLA-DR on classical and non-classical monocytes, seen in 9/23 (39%) and 10/23 (43%) of patients, respectively, correlated

with improved PFS (9.5 vs 3.75 months, $p=0.04$; 11.5 vs 4 months, $p=0.002$, figure 2C and D). No differences were seen after treatment in MDSC or other immunosuppressive cell subtypes. We further performed differential gene analysis of RNAseq data set from paired tissue samples to identify prexasertib-induced tumorous innate immune activation. We found no significant changes in the RNA expression levels of several cytokines known to play a critical role in the innate immune response, including IL6, IL8, IL12, TNF α and IFN γ .²⁹ We also investigated changes in mRNA expression levels of key STING pathway genes, including *cGAS*, *STING*, TANK-binding kinase 1 (*TBK1*) and IFN regulatory factor 3 (*IRF-3*),^{13,30,31} and observed increased expression of *TBK1* among six of nine evaluable patients with paired biopsy samples (median fold-increase 1.14 (1.02 to 1.33)). No other genes were significantly changed. *TBK1* leads to phosphorylation and dimerization of IRF-3 and ultimately induces transcription of type I IFN genes,³¹ and increased expression was associated with improved PFS (9 vs 3 months, $p=0.003$, figure 2E) suggesting STING pathway activation may contribute partly to response to treatment as demonstrated preclinically.¹³ Downstream expression of IFN β was undetectable and expression of the chemokines CXCL10 and CCL5, which are direct targets of IRF-3 and have been shown to increase after STING activation,³² were not significantly different after CHK1i treatment.

Figure 3 Prexasertib-induced changes in adaptive immunity. Paired pre-treatment and post-treatment PBMCs assessed by flow cytometry compared in 23 patients using a Wilcoxon matched-pairs signed-rank test. Lines in A and C-D show median and 95% CI. (A) CIBERSORT analysis to detect immune cell tumor infiltration among nine paired pre-treatment and post-treatment biopsies show an increase in naïve B-cells and resting memory CD4+T cells, and a decrease in the proportion of infiltrating resting mass was observed. (B) Among 12 available post-treatment core biopsies, high (above median) T-reg tumor infiltration was correlated with a significantly worse PFS (9.25 vs 3.5 months, $p=0.007$) using the Mantel-Cox log-rank test. (C) Decreased proportion of CD4+ and CD8+T cells per total viable cells observed from pre-treatment to post-treatment. (D) An increase in the proportion of regulatory T-cells and effector regulatory T-cells among total CD4+T-cells was observed post-treatment. eTreg, effector regulatory T-cell; PBMCs, peripheral blood mononuclear cells; Post-tx, post-treatment; PFS, progression-free survival; Treg, regulatory T-cell.

Immunostimulatory and immunosuppressive adaptive immune responses

To characterize tumorous adaptive immune responses to prexasertib treatment, CIBERSORT, an algorithmic tool that estimates proportions of tumor-infiltrating immune cells using RNAseq data,²³ was utilized on paired tumor biopsies. We found increased proportions of naïve B-cells (0.5% vs 14%, $p=0.003$) and resting CD4 memory T-cells (19% vs 25%, $p=0.03$), as well as decreased resting mast cells after CHK1i (5% vs 0.8%, $p=0.03$) (figure 3A). However, none of these changes were associated with clinical response or PFS, and there was no significant change in activated T-cells. We also noted greater tumorous infiltration by Tregs (median=2.9%, (range 0% to 6.3%)) was associated with a significantly worse PFS (9.25 vs 3.5 months for above versus below median, $p=0.007$; figure 3B), suggesting cross-talk between cell cycle checkpoint inhibition and the adaptive immune response influences clinical activity of prexasertib.

Changes in the peripheral adaptive immune response, including regulatory T-cells (Tregs) and effector T-cells, were compared between pre-treatment and post-treatment PBMCs using flow cytometry (online supplemental table 3). Consistent with the decreased white blood cell count observed in 82% of patients on this trial,¹⁹ CHK1i induced peripheral lymphodepletion, including an overall decrease in both CD4+ and CD8+T cells (25% vs 19.5%, $p=0.008$ and 9.5% vs 7.6%, $p=0.005$, respectively; figure 3C). There was no significant change in the overall proportion of immunosuppressive Tregs or effector Tregs (eTregs), defined as active FOXP3^{high} CD45RA⁻ cells,³³ among total viable cells. However, a slight increase in the proportion of Tregs and eTregs was observed among CD4+T cells (4.8% vs 6.8%, $p=0.01$; 1.5% vs 2.5%, $p=0.009$, respectively; figure 3D), suggestive of an immunosuppressive environment. No significant changes in Ki67+CD4+ or CD8+effector T-cells were observed after treatment.

Next, using the paired tissue RNAseq data set, we evaluated changes in pre-treatment versus post-treatment expression of an INF- γ and expanded immune gene signature incorporating key genes involved in the adaptive immune response²² (online supplemental table 2). No significant changes were observed. Finally, as CHK1i has been demonstrated to modify PD-L1 expression preclinically,^{11–13} changes in expression levels of genes involved in immunosuppression, including PD-1, PD-L1, and cytotoxic T-lymphocyte-associated protein 4 (CTLA-4), were evaluated using RNAseq from nine paired pre-treatment and post-treatment biopsies. No significant changes were observed.

Investigating tumor-infiltrating lymphocytes in archival tissue samples of study patients

To evaluate whether the tumorous immune environment is prognostic and potentially predictive of response to CHK1i, archival tissue biopsies from the time of initial diagnosis (n=21) or recurrence (n=2) available from 96% (23/24) of patients were examined via H&E and immunohistochemistry for the presence of TILs. TILs were evaluable in 21 patients, with two excluded due to tissue fragmentation and lack of stroma, and contained an average of 20% TIL (range 1% to 90% stromal TIL; online supplemental table 4). In line with reports demonstrating an association between TILs and survival in ovarian cancer patients,³⁴ PFS was significantly improved among patients with >30% TIL (13.7 vs 5.5 months, p=0.05). Moreover, the presence of >30% TIL was seen only in patients who experienced a clinical benefit (25% vs 0%, p=0.22) and the tumors of patients who experienced a clinical benefit from therapy showed a trend towards greater TIL compared with those who lacked clinical benefit (27% vs 11%, p=0.07), suggesting TIL levels may serve as both a

prognostic and possibly predictive biomarker, requiring further validation (online supplemental figure 2). Additionally, no association was observed between archival tissue TAMs or PD-L1 carcinoma labeling (positive versus negative) and response to therapy (online supplemental table 4).

Molecular subtypes and correlation with CHK1i response

As the archival tissue immune environment was associated with response to CHK1i, we next assessed whether this was similarly true of pre-treatment tumor biopsies at the time of enrollment. Eighteen available pre-treatment biopsies were classified into four validated transcriptomic molecular ovarian cancer subtypes, which have been shown to carry prognostic and possible therapeutic relevance^{20 21 35} (figure 4). As with previous studies, individual tumor samples expressed multiple signatures at different levels of activation.³⁵ Thirty-nine percent (7/18) expressed high levels of the immunoreactive subtype gene signature, associated with immune response and characterized by enhanced cytokine expression, T-cell activation, and TILs.^{20 35} The immunoreactive subtype did not correlate with PFS or response to CHK1i, possibly due to small numbers.

In addition, the pre-treatment biopsies of the patients with immunoreactive subtype signatures contained more stromal TILs (mean 26% and median 25%) than those with non-immunoreactive subtype signatures (mean 17% and median 10%; p=0.37). Similarly, a higher proportion of pre-treatment biopsies of the immunoreactive subtype signature contained PD-L1⁺ carcinoma cells (68%) than those with non-immunoreactive subtype signatures (38%; p=0.39). These features are indicative of an active immune response.

Figure 4 HGSOC molecular subtype. Expression profiles of the four HGSOC molecular subtypes in 18 available pre-treatment biopsies. Thirty-nine percent (7/19) were categorized as highly immunoreactive (IMR; P4, P10, P33, P1, P36, P23, and P47). DIF, differentiated; HGSOC, high-grade serous ovarian cancer; IMR, immunoreactive; MES, mesenchymal; P, patient; PD, progressive disease; PRO, proliferative; PR, partial response; SD, stable disease.

DISCUSSION

Immune responses to the DNA-damaging drugs is a complex process involving multiple elements within the tumor microenvironment. Thus, it is necessary to translate preclinical findings of immune modulation with CHK1i into the clinical setting given the immune microenvironment observed in preclinical models are often not translatable to humans. We hypothesized that CHK1i would induce DNA damage by impairing the DNA damage repair response pathway, leading to increased tumor immunogenicity in ovarian cancer. For this, we used a variety of methods including flow cytometry, immunohistochemistry, and RNAseq to assess the immune landscape of paired clinical trial patient samples before and after treatment. Our exploratory studies indicate increased DNA damage in immune cells of patients treated with prexasertib, enhanced innate and adaptive immune activity, and a potentially compensatory immunosuppressive response.

The role of the innate immune response in malignancy and the tumor immune microenvironment has been well characterized. MDSCs play an immunosuppressive role and are associated with poor prognosis in ovarian cancer.³⁶ On the other hand, anti-tumor effects of activated monocytes have been reported. In the presence of a tumor, monocytes differentiate into pro-inflammatory M1 macrophages which inhibit tumor proliferation, secrete proinflammatory cytokines, and promote NK cell differentiation for enhanced cytotoxicity.^{37,38} Here, we report that CHK1i treatment led to an increase in the percentage of monocytes among total PBMCs. Moreover, the association between patients with increased HLA-DR positive monocytes and improved PFS suggests that immunocompetent monocytes may contribute to the anti-tumor activity of prexasertib. The STING pathway has been implicated in driving an innate immune response after CHK1i treatment.^{13,39–41} We therefore evaluated changes in mRNA expression levels of key genes related to the STING pathway and PFS. Patients with increased post-treatment expression of TBK1, a downstream protein critical for production of type I IFNs, had improved PFS, indicating STING-pathway activation and innate immunity may be associated with duration of response to CHK1i.

This highlights the question of whether CHK1i also induces alterations in the adaptive immune response leading to clinical benefit in patients. Several studies have shown an association between the presence of TILs and improved patient survival in ovarian cancer.^{42,43} In the present study, although we observed increased naïve B-cell and resting memory T-cell infiltration after CHK1i treatment by CIBERSORT,²³ neither was associated with PFS. However, a greater proportion of T-reg infiltration after treatment correlated with worse PFS, consistent with previous reports.^{44,45} These findings further indicate cross-talk between cell cycle checkpoint inhibition and the adaptive immune response and warrant additional investigation.

Recently, Sen *et al*¹³ reported that CHK1i treatment enhanced anti-tumor adaptive immunity in a STING-dependent manner but in turn led to upregulation of the immunosuppressive cell surface marker PD-L1. We did not observe increases in PD-L1 expression in our RNAseq analysis. However, it is worth noting the possible immunosuppressive adaptive immune changes after CHK1i treatment, requiring further mechanistic studies. Specifically, flow cytometry analysis of PBMCs revealed peripheral lymphodepletion of CD4+ and CD8+T cells, consistent with the leukopenia observed in patients on treatment¹⁹ as well as either selective repopulation with T-regs or selective depletion of effector T-cells in patient samples.

To date, no validated biomarkers have been defined to guide CHK1i therapy. The presence of TILs at diagnosis, but not TAMs, has been associated with improved overall survival in ovarian cancer.³⁴ Our biomarker data also suggest a prognostic association between greater archival tissue TILs, but not TAMs, with longer PFS. This finding should be prospectively tested in a randomized setting for its predictive potential for CHK1i response. Limitations of our study include its small size, the post hoc exploratory nature of this analysis, and all tests reported are without adjustment for multiple comparisons. Therefore, all findings should be interpreted with caution and will need to be validated in a larger, prospective setting. Additionally, while flow cytometry-based detection of γ -H2AX is a validated tool to detect DNA damage and is supported by the observed lymphodepletion after treatment with prexasertib,²⁶ we were unable to confirm CHK1i-induced DNA damage by tissue immunofluorescence due to limited available tissue samples.

The CHK1i prexasertib has marked clinical activity in women with recurrent *BRCA*wt HGSOc.¹⁹ Our exploratory translational studies are the first to report increased DNA damage and depletion of peripheral lymphocytes while apparently activating specific immune subsets that contribute to innate and adaptive immunity in ovarian cancer patients treated with prexasertib. These findings provide insights into the biological effect of CHK1i and present the opportunity to identify potential therapeutic immunotherapy combinations. Further clinical exploration of biomarkers is warranted.

CONCLUSION

Our findings suggest an immunomodulatory role for CHK1i in *BRCA*wt HGSOc patients. Changes in molecular and cellular markers after CHK1i treatment suggest enhanced innate and adaptive peripheral and tumorous immunity as well as a potential immunosuppressive compensatory response. This new clinical insight, supported by preclinical evidence, may identify novel predictive biomarkers for response to CHK1i and supports a differentiated clinical development strategy for therapeutic combinations in ovarian cancer. Further investigation is warranted.

Acknowledgements This research was supported by the Intramural Research Program of the National Cancer Institute (JML, #ZIA BC011525), Center for Cancer Research (CCR). Prexasertib was supplied to the CCR by Eli Lilly and Company under a Collaborative Agreement (Cooperative Research and Development Agreement (CRADA #02915)). This research was made possible through the National Institutes of Health (NIH) Medical Research Scholars Program, a public-private partnership supported jointly by the NIH and contributions to the Foundation for the NIH from the Doris Duke Charitable Foundation (DDCF Grant #2014194), the American Association for Dental Research, the Colgate-Palmolive Company, Genentech, Elsevier and other private donors.

Contributors JML and EJL developed the study and wrote the manuscript. EJL, ACM, JSL, DA, MJL, AY, JBT, JN and ER performed experiments and analyzed data. All authors discussed the results and implications and revised the manuscript. JML supervised the study.
